- Mouginis-Mark and Wilson (2016). Possible sub-glacial eruptions in the Galaxias Quadrangle Mars. *Icarus* 267, 68 – 85.
- Good evidence that this area was once partially covered by ice - based upon current topography and flow paths.
- Galaxias Mons is of intermediate age compared to two major flow events, and that an origin as a hyaloclastite ridge is plausible (Chapman *et al.*, 2000). Role of intrusives for this area is important.

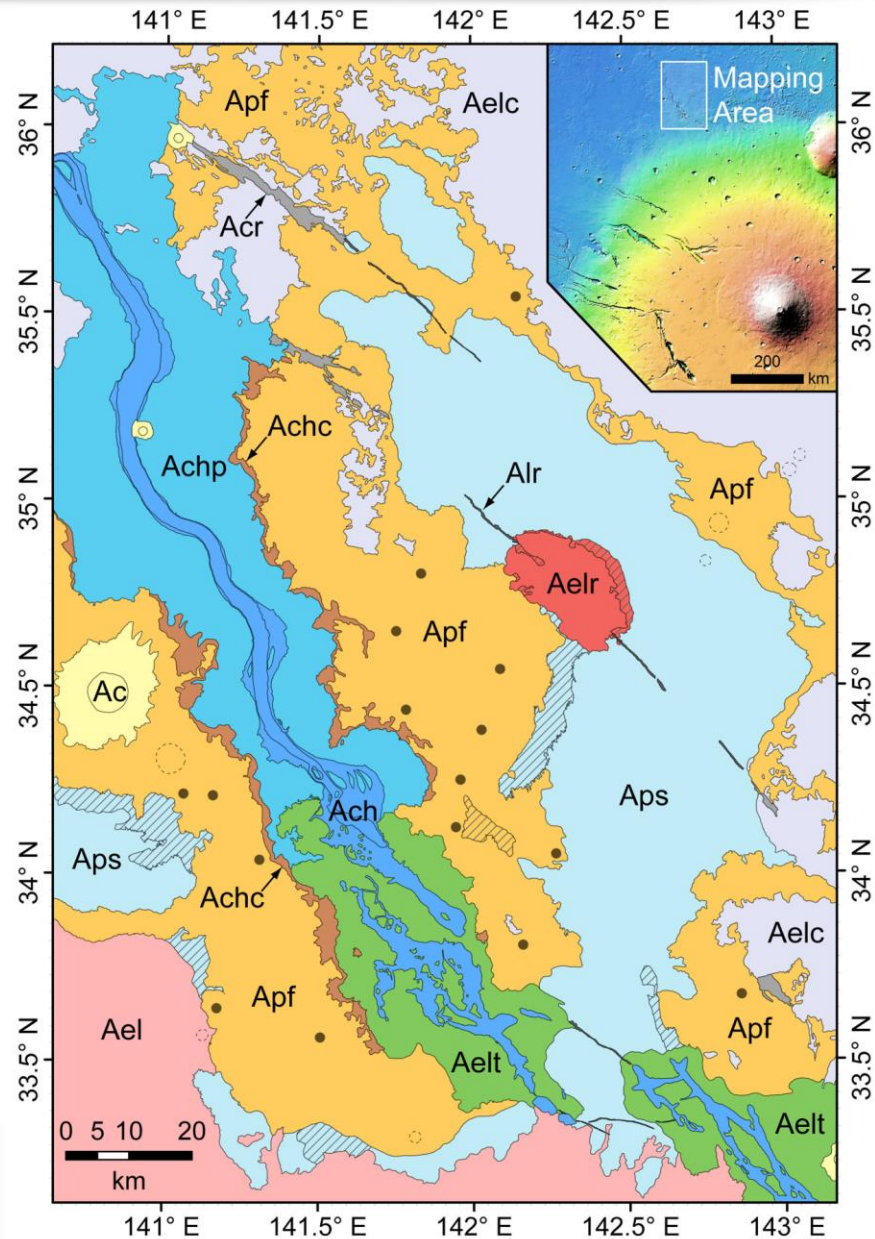

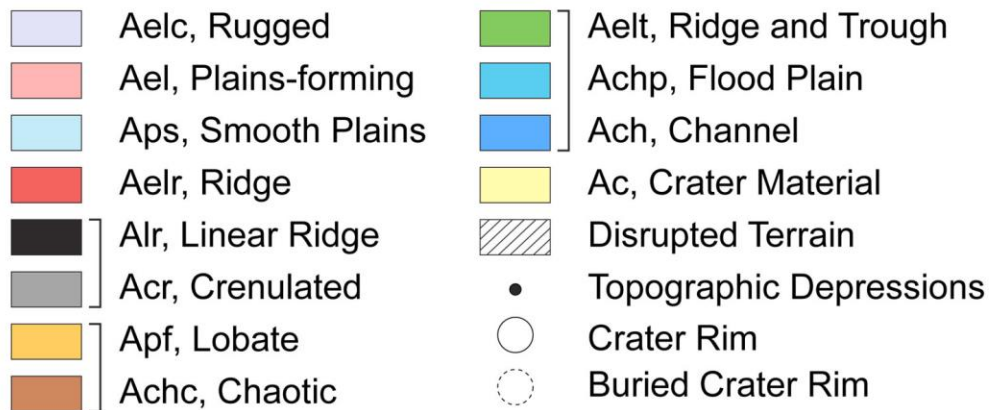

Galaxias Mons

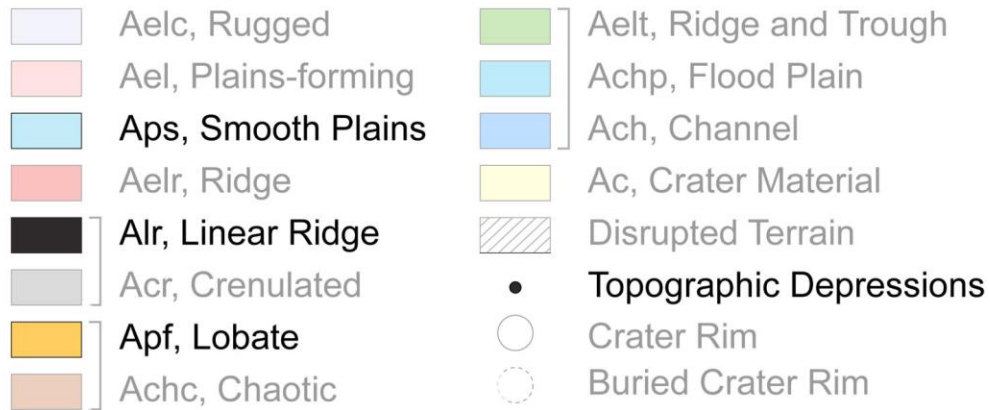

Galaxias Mons 2

New Geological Map of the Hrad Vallis Region

Summary

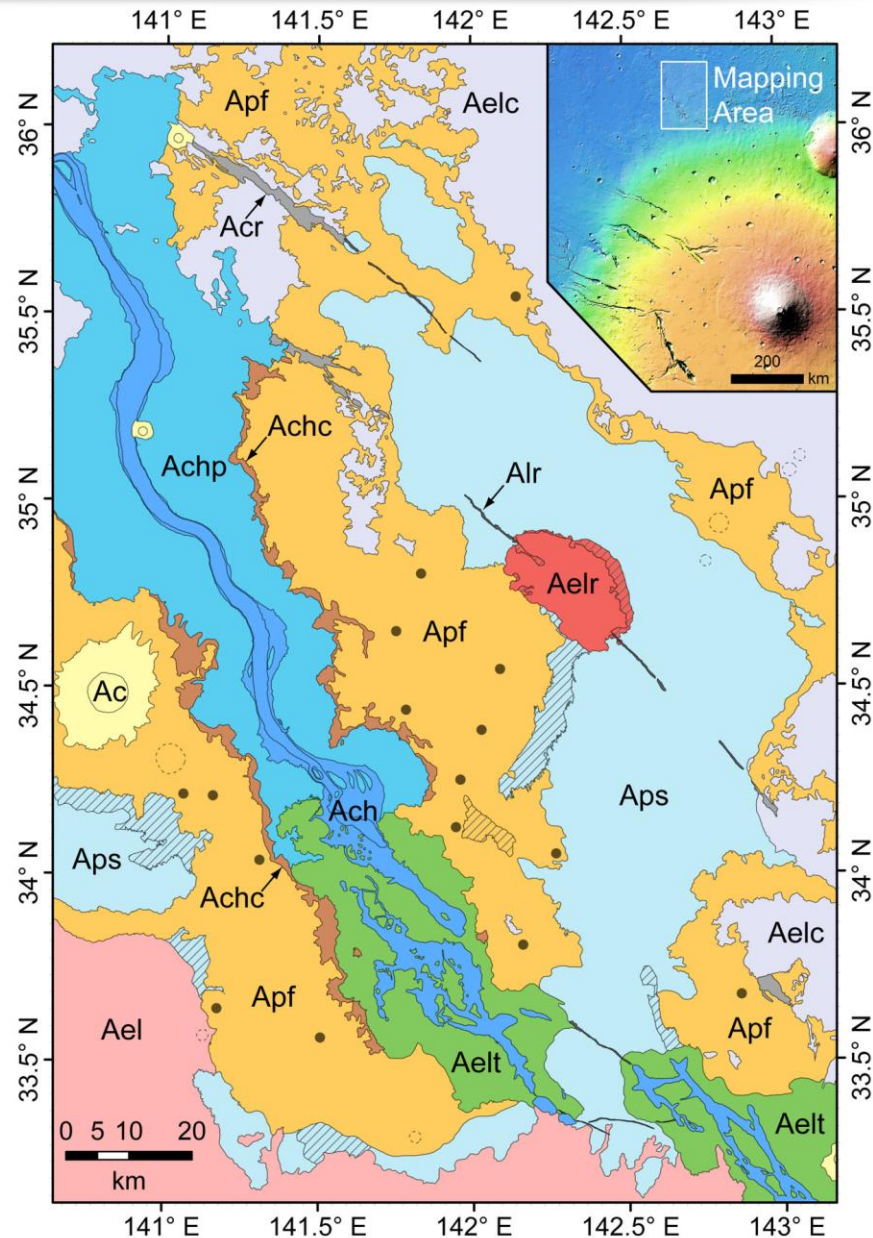

Aps was emplaced as a lahar and froze to form an ice body that gradually sublimed.

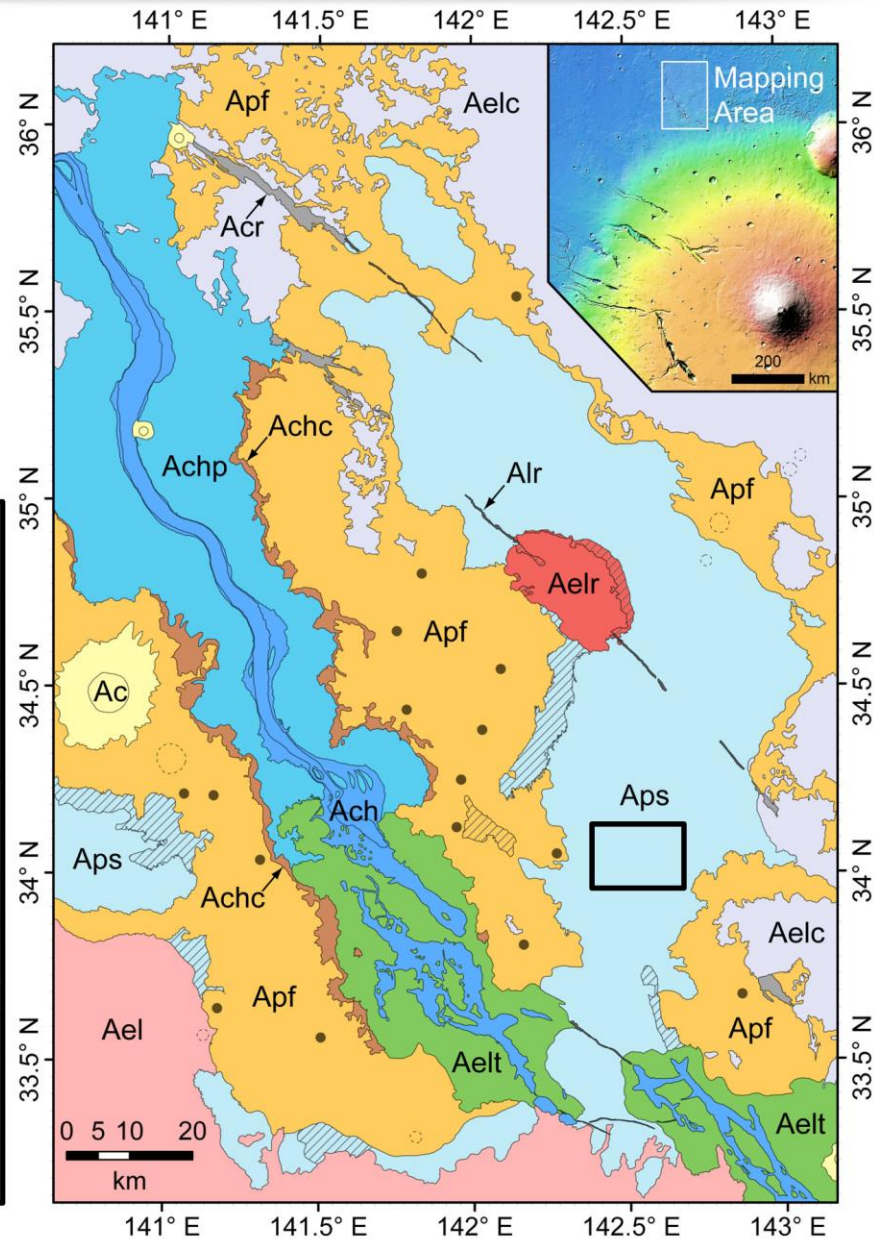

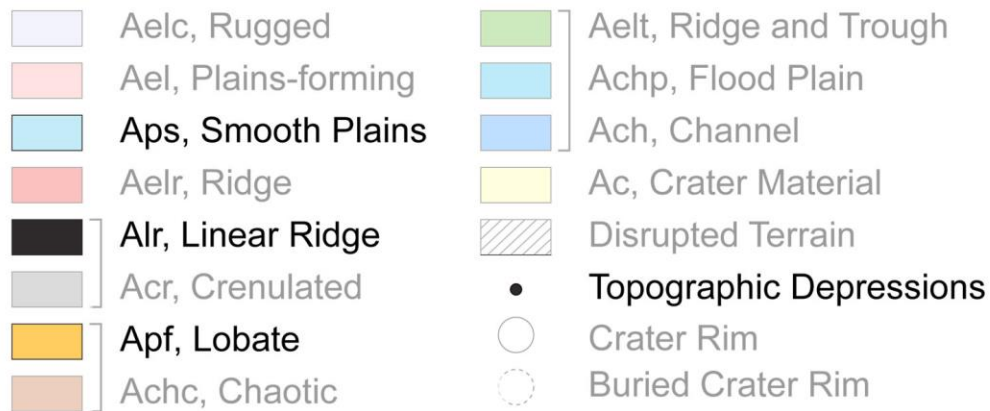

Dikes were intruded into ice to form **Alr**, and were partially exhumed prior to **Apf**.

Apf is an inflated lava flow with lava-rise pits, not a second frozen lahar.

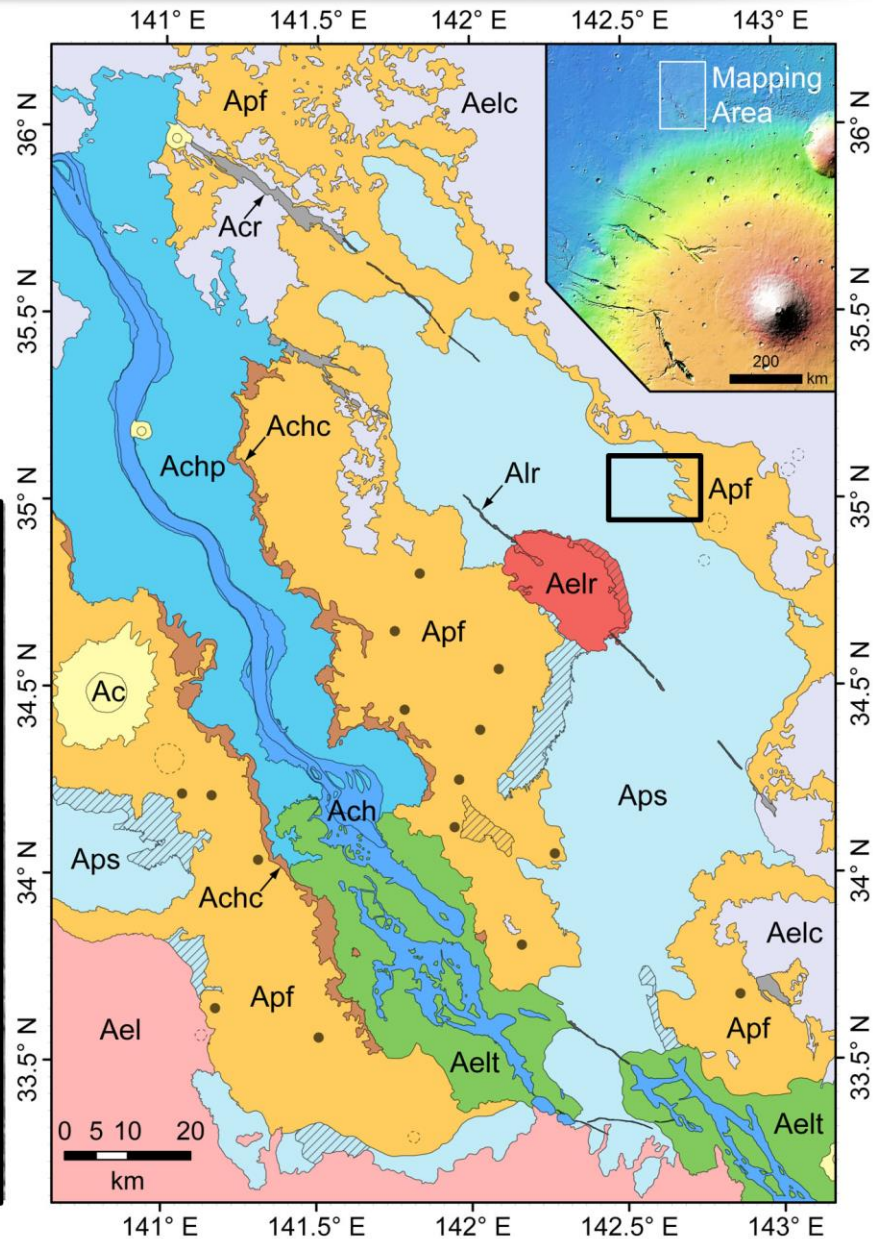

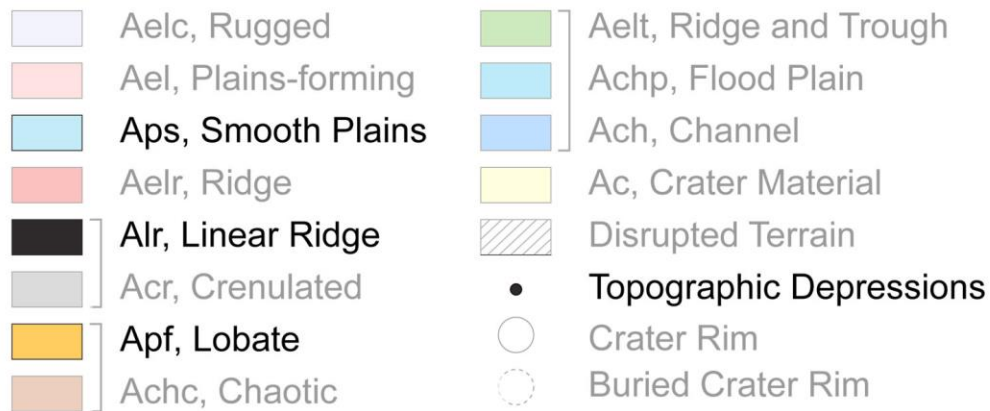

Apf was emplaced in contact with ice to form topographically inverted kipuka and steam explosions.

Testing the Frozen Lahar Hypothesis

Topography

Slope

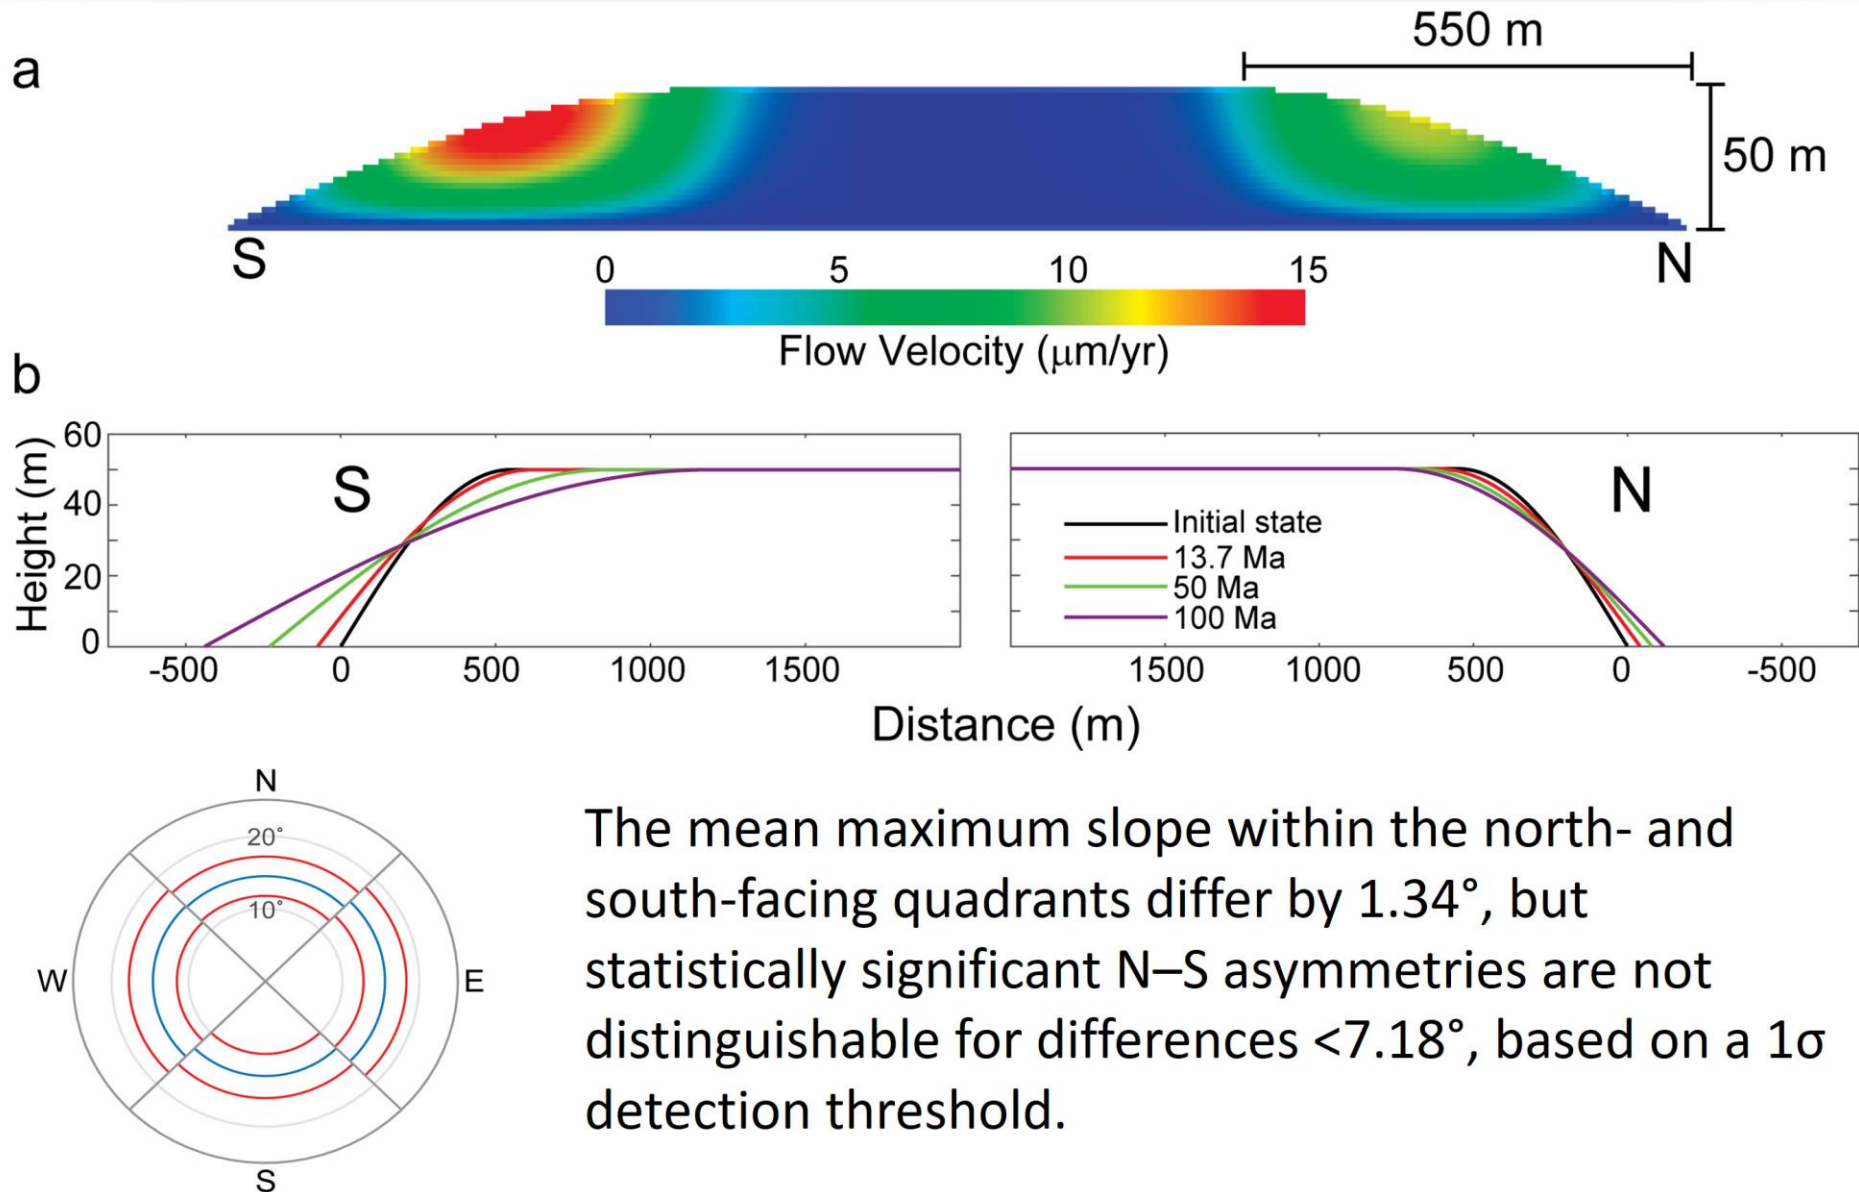

Testing the Frozen Lahar Hypothesis

Cross section through our finite element model showing flow velocities in a pure ice unit with an average temperature of **218 K** on its equatorward-facing (southern) slopes and **212 K** on its poleward-facing (northern) side. The flow velocities for the 40% ice case are 2–3% compared to pure ice case.

Testing the Frozen Lahar Hypothesis

Testing the Frozen Lahar Hypothesis

Blue: Range of ice contents and ages consistent with $1.18\text{--}1.70^\circ$ asymmetry (i.e., mean slope difference $\pm 1\sigma_e$)

Red Line: Conservative case with a detection limit of 7.18° , which is the maximum difference between the mean slopes $\pm 1\sigma$

Conservatively, we conclude that if ***Apf*** is a frozen lahar, **then it is younger than 13.7 Ma** (if pure ice), **younger than 471.3 Ma** (if it contains 40% ice), or potentially older if it was emplaced in the debris flow regime (<40% ice).

Testing the Frozen Lahar Hypothesis

Model runs resulting in 45 m of ice retreat for various sediment contents within ice at 36°N, which provides an upper limit of the age of 45-m-thick ice between 33–36°N.

Testing the Frozen Lahar Hypothesis

Ice Content	Maximum Age for 45-m-thick ice at 33–36°N
99%	510 ka
95%	1.87 Ma
90%	7.5 Ma
80%	13.4 Ma
70%	20.1 Ma
60%	>21 Ma
50%	>21 Ma

Young ages are unrealistic for ice-rich (>70% ice) units because they would sublime away before developing detectable asymmetries by viscous flow.

Ice-poor (<70% ice) units could survive for >21 Ma, but would be expected to generate thick lag deposits, which are inconsistent with observations.

Conclusions

- ***Aps* may be a sublimation lag associated with a former lahar**
- *Apf* provides one of the best examples of an inflated pahoehoe-like lava flow on Mars and a compelling candidate for interaction between a lava flow and surficial ice
- Topographic depressions within *Apf* are consistent with the characteristics of lava-rise pits, and need not evoke a formation mechanism involving impacts into a frozen lahar
- *Aps* and *Apf* do not appear related to the same event
- This implies that Hrad Vallis is a complex outflow channel system generated through alternating episodes of catastrophic aqueous flooding events and effusive eruptions

Conclusions
